Abstract

Aim: The aim of the paper is to explore how self-efficacy is associated with adherence among adults with DM.

Methods: The search of electronic databases identified 564 records from 2007 to 2017 on self-efficacy and adherence from different perspectives and its effect on adults with DM.

Discussion: Self-efficacy increases the confidence in adults in their self-care behaviors. Non-adherence continues to be a significant barrier to self-efficacy. Self-efficacy and adherence should be informed by an understanding of theoretical frameworks and the individual characteristics.

Conclusion: Adherence is likely among adults with better self-efficacy to empower them to make valid decisions about their health. Interventions to improve self-efficacy should be tailored based on different types of non-adherence such as intentional and unintentional non-adherence.

Implications: An inter-collaborative professional practice approach is crucial to improve self-efficacy and adherence for sound judgment and valid decision making.

Keywords: Self-efficacy; Self-care behaviors; Adherence; Chronic illness; Diabetes mellitus; Type 2 diabetes

Introduction

Three hundred forty seven million persons have Diabetes Mellitus (DM) and nearly 3.4 million persons die from complications (World Health Organization [WHO], [1]). Adults with DM have a high incidence of morbidity and mortality as compared to normal or near-normal adult populations. Adults with DM are expected to rise to 350 million cases by the year 2030 [2]. In developed countries, non-adherence to the treatment of chronic diseases ranges from 30% to 50%, and this rate has escalated in the developing countries [3]. Lifestyle factors like behavioral, environmental and societal play a critical part in the prevention of both developments of the disease and its complications [4].

Adults with DM are at higher risk of developing cardiovascular and other secondary complications if the DM is not well controlled [5]. Poor adherence affects self-efficacy leading to lower quality of life and imposes a significant financial burden on the healthcare [6]. Poor adherence and lack of knowledge are key concerns of developing complications and to managing DM. In adults with DM requiring behavior change, self-efficacy and self-care behaviors are central to adherence. Non-adherence to prescribed medications and the lack of awareness are believed to be the common causes of poor treatment adherence among Arab adults.

The Middle Eastern countries will have the second highest increase in the percentage of people with DM in 2030 compared to other parts of the world [7]. In the Sultanate of Oman, approximately 10% of the population is currently living with DM. The number of adults with DM in Oman will rise from 75,000 in 2000 to 217,000 in 2025 [8]. There are very few studies on self-efficacy and the relationship between socio-demographic characteristics and adherence levels of adults with DM in the Middle East [6]. The aim of the paper is to explore how self-efficacy is associated with adherence among adults with DM.

Methods

Several research databases (Academic Search, CINAH, EBSCO, Google Scholar, JSTOR, Lippincott Williams and Wilkins, Medline, ProQuest, PsycINFO, Sage, Science Direct, Springer, Web of Science, and Wiley) were reviewed with keywords for self-efficacy, self-care behaviors, adherence, compliance, chronic illness, adults, and diabetes mellitus. The search of electronic databases identified 564 records from 2007 to 2017 on self-efficacy and adherence from different perspectives and its effect on adults with DM.
Review

Adherence is defined as, an extent to which a person’s behavior-taking medication, following a diet, and or executing lifestyle changes; corresponds with the agreed recommendations from a provider [9]. The concept of adherence implies a mutual and dynamic interaction between the patients and health care providers, and it results in long-term changes in patients’ behaviors [3]. The barriers to adherence are poor knowledge, psycho-social status, the complexity of the disease, co-morbidity, lack of comprehension of treatment, and poor communication between the patient and health-care provider [10].

A qualitative study to explore the possibility of applying treatment adherence success factors in diabetes consultations between health care providers and patients [11]. Patients did not experience goal-setting in consultations. Healthcare providers indicated they motivated patients to set treatment goals. Though shared-decision making was applied, patients were passive collaborators and healthcare providers were in charge of making treatment decisions. An effect of educational interventions on knowledge of the disease, treatment adherence, and control of diabetes mellitus used a pre- and posttest design with the single comparison group [12]. Educational intervention using the cognitive social theory had significantly improved the medication treatment adherence.

An investigation of the DM medication adherence using a theoretical framework, the Health Belief Model (HBM) was conducted in Saudi Arabia [13]. The regression analyses found that most of the adults took the prescribed dose every time taken; however, 60% of these adults were not taking the dose in the prescribed number of times per day and 50%, were not taking the medication in the prescribed time of the day. Perceived susceptibility, perceived medication benefits, and self-efficacy were significant HBM predictors for medication adherence (R2=0.42) [13].

Self-reported adherence rate to anti-diabetic drugs was 84%, and the most common reason for non-adherence was forgetfulness in the United Arab Emirates [14]. This strategy is highly influenced by social desirability responding (faking good), and it depends on memory limitations, especially when asking about behaviors that required adults to remember old practices [15]. Medication adherence of adults with DM in Oman was used to identify the probable reasons for medication non-adherence [6]. Forgetfulness was the most frequent reason for medication non-adherence (36.4%) [6].

Self-efficacy refers to people’s beliefs about their capabilities to produce designated levels of performance that can influence events which affect their lives. Self-efficacy as the ‘belief in one’s capabilities to organize and execute the sources of action required to manage prospective situations’ [16]. Self-efficacy is the central concept that determines individuals’ behaviors and how much effort they spend on adopting the behavior. The perceptions of managing psychosocial aspects of diabetes and readiness to change affect goal attainment in the empowerment model [17]. Higher ability to manage diabetes positively significantly predicts the quality of life and body mass index in the health-related quality of life model [18]. It is significant to recognize paradigms that are pertinent at different phases of readiness for change that are beneficial for self-efficacy. Self-efficacy is the belief that one can effectively achieve the behavior essential to adherence.

Self-efficacy played a critical mediating role between symptoms of depression - a common co-morbidity with DM and glycemic control. Predictors of Self-Efficacy (SE) are demographic and clinical characteristics accounting of 20.6% of the total variance in self-care behaviors and 31.3% of the variance of the SE in the self-efficacy model [19]. Boosting adults’ self-efficacy (confidence) with regard to their ability to implement care successfully is a critical step in promoting active self-management [20]. Behavior change requires some ‘intention’ and ‘intention’ is driven by 3 constructs: attitude, subjective norm, and self - efficacy [21]. Self-efficacy is an important component of management and a key psychosocial variable used in predicting adherence to self - care behaviors.

Central to the theories is the construct of self-efficacy and self-care behaviors and how these influence adherence. Higher self-efficacy is linked with SCB in determining glycemic control and lower HbA1c levels [22]. Education, understanding of DM and management predicted good foot care behaviors in the self-efficacy model [23]. Self-efficacy is the most powerful determinant of intention and suggested attention to self-efficacy. The relationship between these is critical to the improved self-efficacy and adherence among adults with DM.

Discussions

Exploring self-efficacy is critical to achieving optimal adherence among adults with DM. Self-efficacy increases the confidence in adults in their self-care behaviors. The common applications are of social cognitive theory within which the health belief model, the theory of reasoned action, and the theory of planned behavior are most prevalent. The majority of the reviewed studies examining non-adherence has considered it as a single entity and has not differentiated types of non-adherence such as intentional and unintentional non-adherence or the reasons underlying each type [24]. It is very significant to assess before intervene, intentional non-adherence behaviors should be treated differently. Unintentional behaviors such as forgetfulness should receive other strategies to enhance treatment adherence. Non-adherence continues to be a significant barrier to self-efficacy.

Non-adherence concerns all aspects of therapy; not only taking medicines, but also developing self-efficacy and lifestyle changes such as diet and physical exercise, avoiding high-risk behaviors, such as the use of tobacco or alcohol, or simply returning for the next medical appointment [25]. Adults have variant levels in adherence to prescribed treatments. Therefore, the application of theory-driven, evidence-based models is important in the development of effective...
interventions. Self-efficacy and adherence, should be informed by an understanding of theoretical frameworks (e.g., socio-cognitive, self-regulation, and social support), and within those a range of subordinate models (e.g., health belief model, theory of planned behavior, and self-regulation model) and then the individual characteristics (e.g., perceived barriers, perceived benefits, and treatment beliefs).

With aging and baby boomers, demographical and urbanization changes in society, information motivation behavioral skills, it is shown that self-efficacy impacts adherences as shown in the Attachment theory, Epidemiological theory, Theory of reasoned action, Cognitive behavioral theory, Self-care model impacts adherence, and the Medication adherence model. The interventions to improve self-efficacy should be tailored based on the socio-demographic, psychosocial, behavioral, and lifestyle characteristics, the different types of non-adherence such as intentional (e.g., not attending appointments) and unintentional (e.g., forgetfulness) non-adherence of the targeted population.

Conclusion

Adherence is likely among adults with better self-efficacy to empower them to make valid decisions about their health. The socio-cultural aspects of adults in the Middle East are different from the western world in terms of culture, religious nature, spirituality, beliefs, values, education, awareness level, efficacy, compliance and health practices. Providing explanations and predictions about the self-efficacy phenomenon will help to identify barriers and challenges concerning the adherence interpretation. Empirically, cross-sectional descriptive studies guided by behavioral frameworks and self-efficacy models are needed. Building a good knowledge base with clinical trials and behavioral change interventions can be used to test effective interventions that can improve self-efficacy. Health care professionals need to be trained on how to use cognitive behavioral therapies in their communication and consultation with adults with DM. Nurses can make an important contribution to improving self-efficacy among adults with DM. Hence, treatment adherence is a complex and multidimensional phenomenon and is very important to address the concept from self-efficacy. An inter-collaborative professional practice approach is crucial to improve self-efficacy and adherence for sound judgment and valid decision making.
