Clinical, Pathological, Preventive and Therapeutic Aspects in Vulvar Cancer

Victor Manuel Vargas Hernandez*
Gynecology Service, Hospital Juárez de México, Mexico

Abstract

Vulvar cancer is rare, it occupies the Fourth most common type of gynecological cancer that mainly affects postmenopausal women, there is no screening or effective strategies to reduce its incidence, only the timely treatment of predisposing or preneoplastic lesions associated with its development; It can be asymptomatic, most women report chronic pruritus or vulvar pain, or present with a tumor or ulcer; Any suspected vulvar lesion is biopsied(s) to confirm the diagnosis and assess or exclude the invasion. Most vulvar cancer are histopathological type of squamous cell. The most common sub type is Squamous Cell Carcinoma (SCC); it is staged according to the Joint American Committee on Cancer (AJCC) and the International Federation of Gynecology and Obstetrics Systems (FIGO). Surgical staging involves the removal of the primary lesion and the evaluation of the inguino-femoral lymph nodes. In current practice, local radical excision has replaced radical vulvectomy, preserves the anatomy of the vulva and improves wound healing. The treatment of vulvar cancer depends mainly on the histopathological type and surgical staging and is predominantly surgical, particularly for SCC, although Chemotherapy (Qt) with Radiotherapy (Rt), (Qt-Rt) concomitant is an effective alternative, particularly in advanced stages. Women with stage IA vulvar cancer require surgical resection of the primary lesion alone and without Lymphadenectomy (LDN). For stage IB to stage II who are at low risk of nodal metastases (<4 cm, without palpable lateral nodes), a unilateral (ipsilateral) lymph node lymphadenectomy is appropriate and less morbid than a bilateral LDN. If there is evidence of lymph node involvement (stage III) direct extension to the surrounding tissue, or fixed or ulcerated lymph node metastases (IVA stage) are locally advanced. For most patients with locally advanced disease, and primary resection is performed. Primary Qt-Rt or preoperative Qt-Rt followed by conservative surgery are appropriate alternatives when surgery is performed and have evidence of high risk characteristics (i.e. two or more microscopically positive inguinal lymph nodes, one more macroscopically affected lymph nodes, or any evidence of extracapsular dissemination), some experts at (IA stage) recommends adjuvant radiotherapy, are treated with Qt-Rt; when primary Qt-Rt is not technically resectable instead of surgery; when treated with primary Qt-Rt, additional treatment is based on the response to treatment, which is usually completed in 6 to 12 weeks after the end of Qt-Rt; if there is a complete clinical response to Qt-Rt, we suggest recognition instead of surgical treatment; in patients with persistent or progressive disease after Qt-Rt, surgical resection, provided they are candidates for surgery; for local recurrence of the vulva, we offer a new excision, but accept it, the complications that are associated with re-excision (are colostomy, urinary diversion), Rt with or without Qt-Rt is a reasonable option. In metastatic disease, Qt and if they are not candidates or reject it, refer to palliative care is appropriate. If they progress after first-line Qt, palliative care is a reasonable alternative to Qt, especially in patients with severe morbidities.

Conclusion: The management of malignant neoplasms of the non-squamous cell vulva depends on the histological type, but in general, surgery is the primary treatment.

Introduction

Vulvar cancer is rare and accounts for only 2% to 5% of gynecological malignancies. Squamous Cell Carcinoma (SCC) of the vulva, is the most common sub type, is traditionally a disease of postmenopausal women, although the average age of incidence has decreased in recent years due to
the increase in Human Papillomavirus infections (HPV) worldwide 1-13; this epidemiological change makes differences in its current incidence or age of presentation between countries and regions; it can be explained by a different local prevalence of HPV or other Risk Factors (FR); for example, ethnic distribution, smoking, atrophy and inflammation or infection by Human Immunodeficiency Virus (HIV) [1-19].

Anatomy

The external genitals comprise the vulva and pubis or pubic area. The vulva is found in the anterior triangle of the perineum. Elements that make up the vulva include minor and major lips, clitoris, vaginal vestibule bulb and minor vestibular glands (Skene glands) and major (Bartholin glands) [18]. Most malignant tumors are associated with the skin of the lips. Malignant tumors that arise from the clitoris and vestibular glands are extremely rare. The lymphatic drainage of the vulva is mainly to the inguino-femoral region, and secondarily to the external and internal iliac region. This drain is shared with the lower third of the vagina and the outermost part of the anus (under the anal sphincter). Depending on the location of the primary tumor, its size and its proximity to the midline, the lymphatic drainage can be unilateral or bilateral. In addition, if the lesions near or over the clitoris, drainage can be directly to the iliac region [19-21].

Epidemiology

The age-adjusted incidence of vulvar cancer in the United States was 2.5 per 100,000 women. Vulvar carcinoma is most often found in postmenopausal women. The average age at diagnosis is 65 years, but it is decreasing to 55 years [1-13]. Risk factors for vulvar cancer include smoking, vulvar dermatosis (for example, lichen sclerosus lichen or Cervical Intraepithelial Neoplasia (CIN), Human Papillomavirus (HPV), immunodeficiency syndromes, history of cervical cancer Vulvar carcinogenesis is currently divided into two types: The first related to HPV infection of the mucosa and the second related to chronic vulvar dermatoses or autoimmune process. HPV has been shown to be responsible of 60% of vulvar cancer; mainly HPV-16 and 33 representing 55.5% percent of all HPV-related vulvar cancers. There is in incidence of intraepithelial Vulvar Neoplasia (VIN) related to HPV in Young women makes that the average age of diagnosis of vulvar cancer decreases. HPV DNA is common in vulvar cancers of women of late reproductive age with smoking habits, which in postmenopausal women without smoking [1-13].

Clinical Manifestations

The clinical picture of vulvar cancer can be asymptomatic, most women have pruritus; which is common in most vulvar dermatoses; the biopsy is performed when there is a suspicion or the lesions are refractory to vulvar treatment or pain, or have noticed a mass or ulcer. Most are presented with a unifocal vulvar plaque, ulcer or mass (fleshy, nodular, or warty) on the labia majora; Minor, perineum, clitoris and mount of venus less frequently may also have abnormal bleeding or discharge, and many will have a history of vulvar dermatosis symptoms such as underlying lichen sclerosus or high-grade squamous intraepithelial lesion (HSIL) [22-24]. Advanced vulvar cancer can occur with; vulvar bleeding or discharge, dysuria, or groin mass due to lymph node metastasis [5-7,14] or enlarged lymph node in the groin are less frequent; Many patients are asymptomatic at the time of diagnosis. In 10%, the lesion is extensive to determine the actual site of origin. The lesions are multifocal in 5%, the entire vulva and perianal skin surfaces, as well as the cervix and vagina, should be evaluated; there is a synchronous cancer, and it is commonly the CIN in 22%.

Diagnosis

The diagnosis of vulvar cancer is histopathological; vulvar examination with the naked eye or with a magnifying glass is performed during a routine pelvic exam and suspicious lesions include any raised or warty or pigmented lesions. If the injury is not evident, but there is suspicion; the application of 5% acetic acid is performed vulvoscopy (or with a magnifying glass) to define the aceto-white lesions and the underlying vascular changes with abnormal vascular patterns, biopsy is taken, from the area(s) of the abnormal lesion, multiple to "map" all potential vulvar pathology sites not including areas of extensive necrosis [5,9,11-13].

The biopsy is to exclude the invasion. This can be done under local anesthesia with a Keys 3 mm or 4 mm biopsy instrument, or with an incisional or wedge biopsy. Even if the lesion is small, it is better not to remove the entire lesion at the time of the biopsy, as this makes it difficult to plan the definitive subsequent surgery [5,7-14]. If the diameter of the lesions 2 cm or less, and the depth of the stromal invasion is less than or equal to 1 mm at the initial biopsy, it is usual to perform a wide and radical local excision of the lesion to assess the depth invasion maximum if no part of the lesion as a depth of invasion greater than 1 mm, then this excision is the appropriate definitive treatment [22-24] the examinations are as follows:

1. Cytology or cervical Pap test (Pap) and colposcopy of the cervix and vagina, if applicable, due to the association of HPV-related cancers with other SILs.
2. Complete blood count, biochemical profile, liver profile and HIV tests.
4. Computed Tomography (CT) or Magnetic Resonance Imaging (MRI) of the pelvis or groin is useful, especially for locally advanced tumors, to detect any enlarged lymph nodes in the groin or pelvis, erosion in the underlying bone or other metastases; CT or MRI are useful in additional treatment planning.
5. Positron Emission Tomography (PET) with 18F-Fluorodeoxyglucose (18F-FDG) with CT (PET-CT) can more effectively assess and detect the involvement of the inguino-femoral lymph nodes compared to CT, which influences the planning of primary surgery and dissection of the inguinal lymph nodes to determine optimal extension surgery without sentinel node biopsy and use of frozen sections [5,22] PET-CT is used with larger tumors when metastatic disease or recurrence is suspected [2].

Differential diagnosis it includes epidermal inclusion cysts, lentigines, Bartholin gland disorders, acrodermatitis, seborrhoeic keratoses, hydrenomas, lichen sclerosus and other dermatoses, and accumulated condyoma. If one of these disorders is initially suspected, but does not respond to proper treatment [1-15], a biopsy should be performed.

Prevention

Primary prevention (vaccination)

As for cervical premalignant lesions that predispose to cervical cancer, persistent HPV infection, particularly the HPV-16 genotype, has been associated with the long-term development of HSIL and
SCC of the vulva [1,2,23-28]. It has been shown that the introduction of the HPV vaccine as a primary prevention strategy for cervical cancer also reduces the prevalence of non-cervical preneoplastic lesions among women vaccinated [12] in the long term the reduction in vulvar cancer associated with HPV in people vaccinated against and HPV [13,23-28].

**Secondary prevention (screening)**

There is no evidence of specific screening tests for vulvar cancer. Self-examination should be encouraged in women with lichen sclerosus, injury related to the development of vulvar cancer and there should be an early evaluation of any patient with signs (for example, in pigmented lesions, irregular ulcers) or symptoms (such as Pruritus chronic vulvar) commonly associated with vulvar disease, which could be candidates for a vulvar skin biopsy [29-31]. In women with Squamous Intraepithelial Lesion (SIL) of the cervix, vagina or anus they should undergo vulvar inspection as part of the follow-up during the colposcopy exam.

**Tertiary prevention (management of premalignant lesions)**

The effective strategy to reduce the incidence of vulvar cancer is the timely treatment of predisposing and preneoplastic lesions associated with the development of vulvar cancer; there are two main pathological pathways that lead to SCC of vulva [28-31].

1. Keratinizing SCC usually occurs in older women and is often associated with lichen sclerosus and/or differentiated Vulvar Intraepithelial Neoplasia (dVIN).

2. Verrucous/basaloid SCC usually occurs in younger women; it is caused by persistent infection of high-risk HPV (HPV-ar) or oncogenic particularly HPV-16, 18, 31 and 33, and has SIL as its precursor lesion. The lesions are often multifocal and are associated with SIL in other parts of the lower genital tract (for example, cervix, vagina, and anus). HIV infection and smoking are also common predisposing factors [1,3,9].

There are two sub types, both of which usually occur on the lips or vestibule:

Keratinizing differentiated or simple type is more common, occurs in elderly women, is not related to HPV infection, but is associated with vulvar dystrophies such as lichen sclerosus and, in developing countries, chronic granulomatous disease venerale.

The classic, warty, or write bowenoid is primarily associated with HPV 16, 18, and 33, and was found in Young women. The risk factors associated with HPV infection are early age at the first sexual intercourse, multiple sexual partners, HIV infection, and cigarette smoking. These women tend to present with the disease at an early stage, although several cases of stage III/IV of the disease in HIV-infected women have been reported [5]. As shown in Table 1, the terminology and definitions preneoplastic lesions or precursors of vulvar cancer have changed in recent decades. Currently, such lesions that arise from the vulva and anus are included as "inferior anogenital squamous intraepithelial lesions". Under this classification, three subtypes for the vulva are distinguished: Low-grade Squamous Intraepithelial Lesions (LSIL); HSIL; and the differentiated variant. Such a distinction correlates with the risk of developing cancer over time [4-7,30-36].

To date, there is no definitive treatment for conditions such as lichen sclerosus. Standard measures include avoiding exposure to precipitating factors (e.g., local irritant trauma, occlusive wet environment) and powerful and ultra-powerful topical corticosteroids. Alternative options include the use of topical calcineurin inhibitors (e.g., tacrolimus) or retinoids and photodynamic therapy for selected cases and/or cases resistant to corticosteroid therapy. In women, surgery is limited to healing processes that lead to functional impairment [32,33]. Intraepithelial Differeniated Vulvar Neoplasia (dVIN) represents less than 5% of preneoplastic vulvar lesions, characterized by a higher rate of progression to vulvar SCC; the shortest time interval for progression and the higher recurrence rate than HSIL. It is rarely associated with persistent HPV infection (less than 2%). Excision (with margins of 0.5 cm to 1 cm) constitutes the treatment of choice, to allow adequate evaluation and exclusion of the hidden invasion [34-39].

There are multiple treatment modalities for the management of HSIL, but simple excision with 5 mm margins and 4 mm depth is the most common. Excision has the advantage of excluding the invasion histopathologically, but the lack of preservation of the vulvar skin produces psychosexual morbidity, particularly in younger women. An alternative option to preserve the anatomy is the carbondioxide laser, but it lacks the evaluation of the hidden invasion. A less destructive option is the use of 5% imiquimod to prevent scars and sexual dysfunction, particularly in smaller lesions. Moderate quality evidence shows that the response rates with imiquimod and cidofovir, another topical treatment, are similar at 6 months compared to surgical treatment or laser vaporization; there is little evidence of the effectiveness of topical treatment for HSIL among immunocompromised women [34,35]. Regardless of the treatment chosen and the margin status, there is a risk of recurrence (up to 30% to 40%). Therefore, close monitoring is recommended for at least 2 to 3 years [36].

**Vulvar Cancer Stadification**

**Anatomy of the spread of the disease**

**Primary site:** Malignant tumors of the vulva should be confirmed histopathologically and are classified as such when the primary site of origin of the tumor is the vulva. This includes tumors that involve both the vulva and the vagina, but excludes secondary tumors of the genital and extra-genital sites [1].

**Lymph nodes**

The inguinal and femoral nodes are the first sites of dissemination, followed by the pelvis. Depending on the tumor size and its location (closer to the midline or clitoris), the risk of lymph node involvement may be unilateral or bilateral.

Metastatic sites

Women who have lymph node involvement pelvic or extra-pelvic dissemination are considered to have stage IV disease.

Surgical staging

Vulvar cancer has been surgically staged since 1988 and the final diagnosis is based on histopathological evaluation of lymph node and vulvar specimens [1,2]. The staging of the International Federation of Gynecology and Obstetrics (FIGO) [37] of vulvar carcinoma was last reviewed and modified in 2009 by the FIGO Committee of Gynecological Oncology (Table 2) [5-8]. This system is applicable for most malignant tumors that originate in the vulva, except melanoma.

Treatment

The treatment of vulvar cancer depends mainly on histopathology and staging. Other variables that influence the treatment are age, coexistence of comorbidities and the functional status of the patient. The treatment is predominantly surgical, particularly for vulvar SCC, although concurrent Qt-Rt is an effective alternative, particularly when considering treatment options, the most conservative operation that will result in the cure of the disease must be performed [40,41]. More importantly, when considering treatment options, the appropriate treatment for: (1) the primary lesion; and (2) the lymph nodes in the groin, should be considered independently of each other, to maximize the possibility of cure, while minimizing the morbidity related to the treatment [1,2,10,12,40,41].

Carcinoma of Sculose Cells of the Vulva

SSC vulvar surgical management

Radical surgery for vulvar cancer often causes extensive soft tissue defects and, despite the tendency to poor wound healing, requires rapid postoperative recovery to allow adjuvant therapies. Reconstruction ranges from secondary healing to free tissue transfer, with pedicle flaps that are usually the first option. The main objectives of the reconstruction are the cutaneous closure without tension, with good quality tissues, the maintenance of the urethral and vaginal introite without contraction and deviation from its central position, restoration of the anovaginal partition and simultaneous closure of associated defects, such as the pubis or inguinal defects if necessary. In the presence of pelvic exenteration or abdominal-perineal resection, the pelvic support may be affected and a variable amount of devitalized space requires covering it to reduce the risk of complications. Secondary objectives include reconstruction to improve sensitivity, sexual function; aesthetics of the external shape and minimal morbidity of the donor site of the flap [41-49], some drawbacks are mainly due to the size of the defect with minimal consideration for defects associated surrounding, beyond the vulvar and perineal edge. Defects of the groin, pubis, vagina or urethra are often present in gynecological surgery for vulvar cancer; this creates singular geometries of defects that must be considered three-dimensionally as a single form, in order to correctly choose the flap for reconstruction [42-49]; there is a wide arsenal of traditional and piercing flaps. These flaps may be technically demanding but preferable in many cases, due to the longer pedicle, better mobility and decreased morbidity at the donor site. Other very important characteristics that should be considered are: Possible previous Radiotherapy (Rt), laxity of the inner skin of the thigh, often present if the patient is elderly without obesity, asymmetry of the defect, possibly associated abdominal-perineal resection or pelvic exenteration, with the possibility of fecal or urinary stenosis. In the presence of abdominal-perineal resection, anterior pelvectomy or pelvic exenteration, we need to fill the dead space.

In the presence of abdominal-perineal resection, anterior pelvectomy or pelvic exenteration, we need to fill the dead space. Therefore, myocutaneous flaps [5-7,41] the surgical treatment of vulvar cancer must be individualized, and the most conservative operation that will result in the cure of the disease must be performed [40,41]. More importantly, when considering treatment options, the most appropriate treatment for: (1) the primary lesion; and (2) the lymph nodes in the groin, should be considered independently of each other, to maximize the possibility of cure, while minimizing the morbidity related to the treatment [1,2,10,12,40,41].

Vulvar cancer is one of the less common gynecological cancers, and the role of its prognostic factors is unclear [50]. The impact of the age-Adjusted Charlson Comorbidity Index (ACCI) on CSS, cancer-specific survival possibly associated with the highest probability of receiving suboptimal treatment in patients with multiple comorbidities, which increases the risk of disease recurrence and mortality [50], the initial evaluation of the patient, ACCI could be
useful to assess the risk of mortality due to cancer and, ultimately, could be used as a tool for a more personalized and individualized management of the patient.

**Vulvar microinvasive cancer (stage IA)**

Stage IA vulvar carcinoma is defined as a lesion measuring 2 cm or less in diameter, with an invasion depth of 1.0 mm or less. The depth of the invasion is measured from the epithelial-stromal junction of the most adjacent superficial dermal papilla to the deepest point of the invasion [1]. These lesions must be treated with radical local excision and inguinal LDN is not necessary [51].

**Early vulvar cancer**

Early vulvar cancers are those confined to the vulva, and where there are no suspicious lymph nodes, either on clinical examination, or imaging; ultrasound or other [1,15].

The gold standard of treatment for early vulvar cancers is radical local excision or tumor radical. This is as effective as a radical vulvectomy to prevent local recurrence, but substantially reduces the psychosexual morbidity of treatment [5-7,51,52].

The associated pre-invasive disease must also be removed to exclude other areas of invasion and to prevent new tumors that arise in the so-called "abnormal field." While the surgeon must point to surgical margins of 2 cm to achieve pathological margins of at least 8 mm (which allows fixed tissue contraction), it is now recognized that many "recurrent" vulvar cancers are probably new tumors that have developed in the surrounding abnormal tissue, instead of recurrences due to in adequate margins [53,54].

The deep margin of the excision should be the inferior fascia of the urethra or the most adjacent superficial dermal papilla to the deepest junction of the most adjacent superficial dermal papilla to the deepest point of the invasion. While the surgeon must point to surgical margins of 2 cm to achieve pathological margins of at least 8 mm (which allows fixed tissue contraction), it is now recognized that many "recurrent" vulvar cancers are probably new tumors that have developed in the surrounding abnormal tissue, instead of recurrences due to in adequate margins [53,54].

This approach allows for better healing compared to block resection of the vulva and inguinal. Both inguinal and femoral nodes should be removed, since inguinal node dissection alone is associated with a higher incidence of groin recurrence. While some reviews have suggested that Rt alone can control microscopic groin disease, a small randomized trial suggested that dissection of the groin, with postoperative Rt for patients with lymph node metastasis, is greater than the Rt of the groin. All women who have stage IB or stage II cancers must undergo inguinofemoral LDN; LDN is a constant and independent prognostic parameter and allows the stratification of patients in three different risk groups [51-58].

Less than 1% of patients who have small lateral lesions (less than 4 cm and ≥ 2 cm of the vulvar midline) and negative ipsilateral nodes have lymph node metastasis of the contralateral groin and, therefore, an ipsilateral LDN is the appropriate treatment for these patients [8,40,51,53]. Patients who have closer tumors (<2 cm) or that cross the midline, especially those involving the anterior labia minora, and those women who have very large lateral tumors (>4 cm) or lymph node metastasis ipsilateral, must have a bilateral inguinal ginglyon of dissection.

The procedure of sentinel node biopsy in vulvar cancer, sentinel node biopsy is being used more and more in the treatment of women with early vulvar cancer. The objective of the procedure is to detect lymph node metastasis in the sentinel node biopsy (which mainly drains the tumor) and then omit a complete LDN in patients with negative sentinel node biopsy, thus decreasing the morbidity associated with a complete LDN inguinofemoral [21,51]. The indications for a sentinel node biopsy procedure are:

1. Unifocal tumors confined to the vulva.
2. Tumors less than 4 cm in diameter.
3. Stromal invasion of more than 1 mm.
4. Clinically negative groin nodes.

The sentinel node biopsy are identified using radiolabeled technetium and blue dye. There were recurrences in the groin in 2.3% of patients, with a median follow-up of 35 months. The disease-specific SV was 97% after 3 years, and surgical morbidity was substantially reduced. It is noteworthy that when it is not detected in the ipsilateral sentinel node biopsy, a complete ipsilateral inguinofemoral LDN should be performed. If a ipsilateral sentinel lymph node biopsy is positive, a complete bilateral inguinofemoral LDN is recommended [2,55-57,59]. The sentinel node biopsy in vulvar cancer are increasing over time and in older women with comorbidities they are more likely to have a groin evaluation by sentinel node biopsy; but it is not uniform in all centers and barriers to its realization must be explored. Predictive factors of prevalence and extent of N+ in vulvar cancer, invasion of the lymphovascular space, tumor stage, age and depth of infiltration are associated with the prevalence of lymph node metastasis; the stage and tumor size are associated with the number of lymph node metastasis [57,59,60-62] sentinel node biopsy.

In particular, the early stage of the management of patients with inguinal lymph node metastasis [37,51-57] showed that when they had >1 lymph node metastasis in inguinal LDN, they had better results with pelvic and inguinal adjuvant Rt compared to pelvic LDN. Women with lymph node metastasis who received targeted adjuvant Rt improve survival [56].

The prognostic importance of the number and size of inguinal lymph node metastasis, as well as the presence of extracapsular dissemination. Patients with small lymph node metastasis appear to have a good prognosis after inguinofemoral LDN alone, unless there is extracapsular dissemination, and these women do not appear to benefit from adjuvant Rt, indications for pelvic and inguinal Rt [56,61,62] in patients with lymph node metastasis they are:

1. Presence of extracapsular dissemination.
2. >2 lymph node metastasis inguinals [40,41].

Patients who have a positive sentinel node biopsy (>1 lymph node metastasis, in addition to performing a complete dissection of the inguinofemoral lymph nodes, should receive Rt in the groin and pelvis, if indicated. The efficacy of groin Rt without inguinofemoral LDN for patients with only 1 ganglion in the sentinel node biopsy sentinel node biopsy of 2 mm or less in diameter [40-42,46,51,52].

In terms of Rt, the radiation fields during External Beam Rt (EBRT) should include the inguinofemoral and external and internal iliac lymph nodes in most patients. If there are many bulky positive inguinal nodes or if pelvic lymph node metastases are suspected, the upper edge of the radiation field may extend [61,63] Sometimes, brachytherapy can be added as an impulse to an atomically susceptible
primary tumors.

There are a variety of Rt techniques to choose from, depending on the size, shape of the patient’s body, and extent of the disease (for example, 3D-shaped fields 7 Anterior-Posterior/Posterior-Anterior [AP/PA], Rt de modulated intensity therapy [IMRT]). To ensure adequate tumor coverage, clinical examination, imaging findings (CT or MRI) and nodal size should be considered to adequately define the target volume during 3D planning [43-45,51-55,61-63].

Combined photon and electron techniques are often used to treat regional nodes, without overdosing the femoral heads. It is important to properly include both superficial and deep inguinal lymph nodes. Under dosing of the superficial inguinal ganglia by high-energy photon beams is a risk in thin patients, and care must be taken to avoid this. Enough energy must be used to cover the femoral nodes, if electron beams are used [5,22,43-45].

IMRT or other computer-controlled and reverse-controlled radiation management techniques are more modern methods that have been used in recent years to treat vulvar cancer. The benefits of this are the reduction of the adverse effects of acute Rt on the skin and soft tissues, but as the treatment planning and administration of IMRT are complex, and the risk of under-dosing is substantial, these techniques are better used by doctors who have the necessary experience [22,43-45].

The dose of Rt is determined by the initial extent of the disease and any known residue. After a groin LDN where microscopic inguinal metastases are found, 50Gy in fractions of 1.8Ggy to 2.0Gy are usually sufficient. In the case of multiple N+ or extracapsular dissemination, doses of Rt of up to 60Gy can be administered at a reduced volume. Macroscopic residual disease generally requires 60Gy to 70Gy to achieve a high probability of regional control of the disease [5,22,43-45]. Women with vulvar cancer with lymph node metastasis benefited more from the addition of Qt to Rt [49].

**Advanced vulvar cancer**

Advanced vulva cancer includes tumors that extend beyond the vulva and/or where there are bulky lymph node metastasis in the groin [5,22,37]. The treatment of women with advanced vulva cancer is complex and should be individualized and performed by a multidisciplinary team. When faced with advanced vulva cancer, the ideal is to determine the lymph node state before planning treatment [29,41,44,54]. Patients with Clinically suspicious nodes should have fine needle aspiration or lymph node biopsy, and pelvic CT, MRI or PET-CT may be useful in determining the extent of inguinal and pelvic lymphadenopathy and the presence of metastatic disease a distance [5,22,43-45].

If there are no suspicious nodes, either clinically or in images, bilateral inguinofemoral LDN can be performed, and if the nodes are negative, Rt in English and pelvic nodes will not be necessary, if histology reveals positive nodes, then it should be offer adjuvant radiation to the groin and pelvis for early stage disease [51]. In cases where surgery is considered in appropriate for the individual patient, primary Qt. Rt can be used to treat the primary tumor, as well as the groin and pelvic ganglion [59,61].

In patients with lymph node metastasis, the enlarged groin and pelvic nodes should be removed if possible, and the patient should be given postoperative inguinal and pelvic Rt. Complete LDN should not be performed because a dissection of the entire groin followed by Rt of the groin can cause severe lymphedema. The fixed or ulcerated lymph nodes in the groin should be biopsied to confirm the diagnosis, and then treated with primary Rt, with or without Qt; if there is an in complete response to Rt, the nodes can be resected if appropriate [62]. In terms of the treatment of the primary tumor, surgical excision of the primary tumor with clear surgical margins and no sphincter damage, whenever possible, constitutes the optimal way to treat advanced vulva cancer, as well as to alleviate symptoms such as local and offensive pain [5,22]. If proper removal of the primary tumor can only be achieved by exenteration and the formation of a bowel or urinary stoma, radiation therapy (with or without concurrent Qt) may be a preferred treatment alternative. Survival improves if any residual post-Rt [62] tumor is resected. Concurrent Qt-Rt is a well-described treatment alternative for those patients with large tumors in whom primary surgical resection would damage the central structures (anus, urethra), and have reported full long-term responses [5-13]. The groin and pelvis nodes may need to be included in the radiation field depending on the state of the groin nodes [60-62]. It has been reported that neoadjuvant treatment with cisplatin and 5-fluorouracil, or other combinations of Qt, is effective for the preservation of the anal sphincter and/or urethra in patients with advanced vulva cancer.

In relation to the planning of Rt in advanced vulva cancer, if the lymph node metastasis in the groin and comply with the indications described above for adjuvant Rt, the treatment fields of Rt should include the pelvis, inguinal and vulva. These should be treated with a total dose of at least 50Gy, with attention to adequate coverage of the inguinal nodes [62].

Severe disease or high-risk areas can be enhanced with appositional fields of selected electrons to provide a suitable dose to the surface and in depth, or with a conformal external beam therapy. Large vulvar tumors probably require 60Gy to 70Gy to achieve local control, although the relationship between dose and local control remains the subject of ongoing research [62,63].

**Close surgical margins**

Most recurrences of vulvar cancer at the same site in the vulva. It is believed that surgeons should aim for tumor-free pathological margins of 8 mm or more to minimize local recurrence of the disease. Multiple retrospective studies have tried to evaluate the factors that can determine vulvar recurrence, and other clinical determinants have been suggested in addition to in adequate excision margins, although it is not clear which combination of factors is more significant [63-69]. Two types of local recurrences were described, those of the same site as the original (primary) tumor and those of a different vulvar site. An analysis of patients with vulvar cancer showed that recurrences at the primary site occurred with a mean disease-free interval of 21 months and were associated with a histopathological margin of 8 mm or less, as reported in several other documents [22,53]. “Recurrences” in remote vulvar sites occurred later, with a mean disease-free interval of 69 months, and were more commonly associated with lichen sclerosus [40-42].

Since most vulvar squamous carcinomas arise in an atypical skin found such as HSIL, lichen sclerosus and dVIN, and as they characteristically recur locally but often in remote sites of the original tumor, it is suggested that many 'recurrences' may actually be secondary. Primary tumors, which arise in a "cancer field", an area of genetically altered preneoplastic epithelium that has a predisposition to undergo a malignant transformation [40-43].
Patients with close surgical margins (less than 5 mm) benefit from postoperative radiation therapy (RT) if it is not possible to remove the margins. A study of 205 women with vulvar cancer reported that margins of 5 mm or less represented the highest risk of vulvar recurrence, and that patients who received a dose of more than or equal to 56 Gy had a lower risk of relapse than those who received less than or equal to 50.4 Gy [5-13,68]. Occasionally, positive margins can be increased with brachytherapy, although care must be taken to avoid the risk of necrosis. An alternative is to treat the surgical bed with an appositional electron field or with external beam RT according to [61]. In recent years, efforts have been made to individualize and reduce radical treatment, with special emphasis on Quality of Life (QOL) after treatment of patients [10-13], (Figure 1).

Rare Vulvar Malignancies

**Melanoma of the vulva**

Vulvar melanoma is the second most common vulvar malignant neoplasm. Any pigmented vulvar lesion should be biopsied or removed for diagnosis, unless it has been present and has not changed for some time [39]. Most vulvar melanomas involve the clitoris or the labia minora [22]. Clark or Breslow modifications of the system of staging, as included in the American Joint Committee on Cancer (AJCC) system and based on the depth of invasion, should be used for staging these lesions instead of the FIGO staging system, as it is the only system prospectively proven to correlate with recurrence and survival [69].

Surgery is the treatment of choice for vulvar melanomas. The lesions should be treated by an anterior and radical, with margins around the lesion of at least 1 cm [22]. The current trend leans towards a more conservative resection of vulvar melanomas because no difference in survival has been found in patients undergoing local excision versus those with radical vulvectomy [70,71].

The role of lymphatic dissection (LDN) is also controversial and, to date, no advantage has been demonstrated in survival for inguinal LDN [71], although the prospective, randomized, multi-institutional study of the Inter Group Program of Surgical Melanoma, elective LDN versus Observation of intermediate thickness (1 mm to 4 mm) cutaneous melanomas revealed that elective LDN resulted in a significantly better survival for patients 60 years of age or younger, patients with 1 mm to 2 mm thick tumors, and patients without tumor ulcer. Sentinel node biopsy has also been screened for vulvar melanoma, and although it is feasible, a false negative rate of 15% has been reported; it has been suggested that the procedure may increase the risk of locoregional recurrences and, therefore, is not a current standard practice [72-74].

**Bartholin Gland Cancer**

Bartholin gland carcinomas are rare forms of vulvar cancer; some are associated with HPV-α; the age varies from 38 to 72 years (with an average of 58.3 years); they are typically deep within the vulva and diagnosis is frequently delayed; as the extension to the overlying skin is a late manifestation and the extension through the Bartholin duct to the vagina, with the consequent bleeding as a presenting symptom is generally according to the tumor size; that this mass of the Bartholin complex is often diagnosed as Bartholin abscess or cyst; 50% of complex Bartholin cancers are of squamous histology and are believed to originate in the Bartholin duct instead of the gland. The rest includes a variety of rare adenocarcinomas including adenoid/cystic carcinomas with indolent natural history, proneness to perineural invasion, and rare lymph node spread. All SCCs of the Bartholin gland expressed p16 diffusely and intensely regardless of histological characteristics and grade; they support the etiological role of HPV in the pathogenesis of SCC of the Bartholin gland. Bartholin gland cancers can be transitional cells or SCCs that arise from the duct, or adenocarcinomas that arise from the glands. There are also cystic and adenosquamous adenoid variants. All SCCs showed a diffuse and intense p16 expression consistent with the presence of HPV [70,75]. Most are in the early stage. The average clinical follow-up was 53.7
months (range, 3-181 months), they are disease free (75%).

Diagnosis is often made after resection of a persistent or recurrent Bartholin cyst [22]. The traditional approach to therapy is radical vulvectomy with bilateral and pelvic inguinal LDN or with a radical hemi vulvectomy and a bilateral groin LDN; Due to the location of these tumors, deep in the ischioanal rectal fossa, adequate surgical margins are difficult to achieve and postoperative Rt decreases the probability of local recurrence and adjuvant Rt is recommended for positive margins or perineural invasion [75].

A complete excision of the disease often requires extensive and deep dissection. Less radical cleavages, such as local radical excision or partial vulvectomy with ipsilateral inguinal LDN or with a radical hemi vulvectomy and a bilateral groin LDN; Due to the location of these tumors, deep in the ischioanal rectal fossa, adequate surgical margins are difficult to achieve and postoperative Rt decreases the probability of local recurrence and adjuvant Rt is recommended for positive margins or perineural invasion [75].

For advanced disease, individual case reports describe the activity for liposomal doxorubicin and paclitaxel [5,22,75,76].

Warty carcinoma

Radical local excision is usually adequate, such as locally invasive warty carcinoma, but rarely metastasizes. Suspicious lymph nodes should do a biopsy; if positive, theninguinofemoral lymphadenectomy is indicated. Rt is contraindicated because it is thought to induce anaplastic transformation and increase the probability of metastasis, but there is no evidence. Recurrences are usually treated with surgery [5,22].

Paget’s disease of the vulva

Paget’s disease is rare and affects the apocrine glands of the vulva. There are two types: the primary form begins as an intraepithelial lesion, but the secondary form is due to the invasion of an underlying adenocarcinoma, which can be anorectal, urothelial or genital tract carcinoma (for example, endocervical or endometrial) [77,78]. Paget vulvar disease occurs predominantly in postmenopausal women who present with vulvar pruritus and pain and, on examination, an eczematoid suppurative lesion is often observed. The diagnosis is usually confirmed by a biopsy, which will also help to differentiate between an intraepithelial and invasive lesion [24].

The treatment of choice for intraepithelial Paget’s disease is wide local excision. Clear margins are difficult to achieve since histopathological changes often extend well beyond what is macroscopically visible; even with adequate margins, recurrence rates are high. Treatment with Mohs micrographic surgery (i.e., microscopically controlled systematic excision of cancerous tissue) may be associated with a lower recurrence rate, particularly for recurrent tumors [5,22].

Due to the high recurrence rate and surgical morbidity, there is a current movement to perform a less radical resection for intraepithelial lesions, with a new excision at a later date if the lesions recur. Lesions involving the urethra or anus also present a management challenge and require laser therapy [20]. Another conservative treatment option is local imiquimod [5,22]. A Cochrane meta-analysis that investigated treatment options concluded that there was no “better” intervention for Paget vulvar disease [77]. If there is an underlying adenocarcinoma, the treatment should be a radically wide local excision with margins of at least 1 cm. Ainguineofemoral LDN should be performed, with adjuvant Rt for the same indications as for squamous carcinomas [78-81].

Sarcomas

Wide local excision is the standard method, lymph node metastasis are uncommon. Among the most common histological types are angiomyxoma and rhabdomyosarcoma; the latter is diagnosed in children. Surgical treatment is usually accompanied by preoperative or postoperative radiotherapy in analogy with the treatment of limbs and soft tissue sarcomas in anatomical sites where wide surgical margins cannot be obtained significantly absent, debilitating sequelae such as amputation of limbs [5,22,81].

Basal cell carcinoma

Basal cell squamous carcinoma or Basosquamous Cell carcinoma (BSC), represents 2% of vulvar cancer, affect postmenopausal Caucasian women can be locally invasive; although, without metastatic; its typical appearance is the ulcer with irregular central borders; the lesion may be pigmented or pearly or gray. They are often
asymptomatic, but itching, bleeding or pain may occur; associated with a high incidence of antecedent or concomitant malignancy in other parts of the body, a thorough search of other primary malignant tumors should be performed [5,22,81].

**Histopathological Considerations**

In relation to simple analyzes, the following should be taken into account [29-31]:

1. Orientation: The correct orientation of the surgical piece is important.
2. Photographs: Of the complete sample, of the origin of each tissue block.
3. Measurements: Sample size, dimensions of any visible tumor, tumor-free Macroscopic margins and tumor depth (sections taken through the tumor). Sections should also be taken from the urethral, anal and vaginal resection margins.
4. Lymph nodes: The site from which they were removed must be dissected; a complete cross section of each lymph node must be embedded.

The following histopathological points [27-31] should be taken into account:

1. Type of tumor.
2. Depth of invasion: Measured from the epithelial-stromal junction of the adjacent dermal papilla to the deepest point of invasion by the tumor.
3. Tumor grade.
4. Histopathological measurement of tumor-free margins and declaration of whether the tumor is completely removed.
5. Presence or absence of perineural lymphovascular space invasion.
6. Nature of the adjacent squamous epithelium, for example, dVIN, lichen sclerosus and changes associated with HPV.
7. Sites and number of nodes examined, number of lymph node metastasis and presence or absence of extracapsular extension.

**Dissemination Mode**

Vulvar cancer metastasizes by a variety of mechanisms. Understanding these potential pathways is important for the evaluation and treatment of these tumors; the spreads include:

Direct extension to adjacent structures (for example, the vagina, urethra, clitoris, anus).

Lymph node regional lymph nodes may occur early in the course of the disease, even in patients with small lesions; 10% of superficially invasive vulvar cancer (lesions >1 but <3 mm of stromal invasion) had lymph node metastases at diagnosis [29,31,41]. Most vulvar cancers first spread in the lymph nodes in the groin (inguinal-femoral), so these nodes are sampled as part of staging. Lesions found on one side of the vulva generally spread only to the ipsilateral inguinal nodes.

**Postoperative Complications**

In vulvar cancer it is relatively high. The rate of complications of the vulva in the wound varies from 9% to 58%, while frequent urination or urinary incontinence are confirmed in 8% to 28% of cases. The frequency of inguinal complications after inguinal lymphadenectomy is reported as 21% to 39% for infection, 17% to 39% for wound dehiscence, 21% to 57% for cellulite, 11% to 40% for lymphocele, and 14% to 48% for lymphedema. Most cases of lymphedema occur in the legs with in the first 12 months after surgery and are chronic. Lymphedema is aggravated by obesity, infection, the addition of radiotherapy and deep vein thrombosis after surgery [29,31,41,46]. In addition, psychological and social problems occur frequently after surgery for vulvar cancer, including psychological stress, pain during sexual intercourse, decreased libido, frequent urination and incontinence. Because these problems are detrimental to the quality of life of a patient [41,46,53,57].

**Local Recurrence**

Treatment recommendations for patients with recurrent vulvar cancer take into account the patient's functional status, previous treatment modalities received, and recurrence sites [42].

Vulvar cancer recurrences are classified as (n primary or residual tumor bed in the vulva) or local, regional (in ganglia) or distant (hematogenous). The distribution of recurrences in 37% of which recurred after primary oncological (surgical) management: local recurrences in vulva or inguinal regions in 53 and 19%, respectively. The recurrences to distant involved the pelvis or extra-pelvic in 6 and 8%, respectively and the multiple recurrences [53,55,56] in 14%.

**Metastatic Disease**

For patients with recurrent disease that involves the pelvic region, multiple sites and/or distant metastatic disease, we offer chemotherapy, provided that the patients are candidates for systemic treatment. If patients are not candidates for or reject systemic treatment, referral to palliative care is appropriate.

There are no prospective first-line chemotherapy trials for this population. Therefore, we extrapolate our treatment of metastatic cervical cancer management, in which platinum-based treatment is routinely administered in this environment [10]. Our preference is to administer carboplatin plus paclitaxel because this combination has been shown to be better tolerated than cisplatin plus paclitaxel.
in a trial of women with metastatic cervical cancer, there is little data on the efficacy of the first and adjuvant Qt. The Qt-Rt that are active in other types of squamous cell cancer are not as active in vulvar metastatic carcinoma [22]. Women who are not candidates for chemotherapy due to comorbidities or poor general condition should receive palliative care. For these patients, Rt can provide relief to symptomatic sites [10,22,42,53,55,56].

Follow-Up and Surveillance after Treatment

The majority of vulvar cancer relapses occur in the first year, 10% had a second malignancy diagnosed ≥ 5 years after initial treatment, demonstrating the need for long-term follow-up; interrogating, the symptomatology and performing exploration of the vulva, skin and inguinal nodes; in early stage, it is done every six months during the first 2 years and then annually; in advanced stage, every three months for the first 2 years, and then every six months for 3 to 5 years, and then annually (the Pap cervical or vaginal if the cervix has been removed annually). Routine use of imaging studies should be avoided. Most salvageable recurrences are easily detected by Physical examination. If recurrence is suspected, computed tomography and/ or positron emission tomography are performed, colposcopy and vulvar biopsy are indicated when abnormalities are observed on physical examination [79-81]. Sexual dysfunction and alterations in body image are common after treatment and should be addressed during follow-up visits [22].

Conclusion

Vulvar cancer is one of the less common gynecological cancers, and the role of its prognostic factors is far from clear; is associated with a greater probability of receiving a sub optimal treatment in patients with multiple comorbidities, which increases the risk of disease recurrence and mortality because vulvar cancer is difficult to perform a prospective evaluation of prognostic factors, age represents a confusion factor when assessing the impact of comorbidities on survival, to be used as a tool for a more personalized and individualized management of the patient.

Histopathological Types

SCC of the vulva represent the vast majority of vulvar cancers (more than 80%), and melanomas are the next most common cancer. The rarest histopathological types include:

1. Basal cell carcinoma
2. Verrucous carcinoma
3. Paget’s disease of the vulva
4. Adenocarcinoma, not otherwise specified
5. Bartholin gland carcinoma

Histopathological Degrees

1. GX: the grade cannot be evaluated
2. G1: well differentiated
3. G2: moderately differentiated
4. G3: poor or undifferentiated

Vulvar Biopsy; Stromal invasion; Local split; Simple vulvectomty; Lateral lesion.
