Abstract

External biliary drainage is a necessary procedure in some situations, particularly in tumor obstructions of the bile ducts. We report the case of a 51-year-old man with hyponatremia and functional renal failure after high-volume biliary excretion following external percutaneous transhepatic biliary drainage for an obstructive Klatskin tumor. Our case shows that internal drainage should be preferred to external drainage which is a source of hydro electrolyte and circulatory complications that can be life-threatening.

Keywords: External biliary drainage; Hyponatremia; Renal failure; Klatskin tumor; Jaundice

Introduction

The majority of biliary obstructions of tumor origin are unresectable at the moment of diagnosis, thus requiring biliary drainage for palliative purposes; at best internal drainage. Otherwise, external drainage may be necessary [1]. During external biliary drainage, the amount of bile fluid drained daily varies between 200 mL to 1,600 mL. However, higher volumes have been described in some cases in the literature [2].

We report the case of a patient who underwent external biliary drainage for a Klatskin tumor, with a high biliary drainage rate, leading to hyponatremia and functional renal failure.

Observation

A 51-year-old man was admitted for frank cholestatic cutaneous-mucous jaundice (dark urine, discolored stools and generalized pruritus) which had progressed for 3 months. He also had mild to moderate epigastralgia with no aggravating or relieving factors. He reported 16 kg weight loss in 3 months. He had no other associated symptoms. He had no specific medical history and was not taking any treatment.

The biological assessment showed biological cholestasis: Hyperbilirubinemia at 276 mg/L predominantly conjugated (230 mg/L), Alkaline Phosphatases (ALP) elevated to 1,172 U/L (9.8 times the upper reference value) as well as an increase Gamma-Glutamyl Transferases (GGT) at 2,528 U/L (35 times the upper reference value), associated with minimal cytolysis: ASAT at 107 U/L (2.1 times the upper reference value) and ALAT at 115 U/L (2.8 times the upper reference value). The rest of the laboratory tests showed hemoglobin at 13.4 g/dl, leukocytes at 6240/µl, a slightly elevated C-Reactive Protein (CRP) (16 mg/L), a normal level of prothrombin (78.2%), serum sodium was 136 mmol/L and serum potassium 4.2 mmol/L. Creatinine was 8 mg/L and urea 0.5 g/L.

An abdominal ultrasound performed showed dilation of the intrahepatic bile ducts, most likely by compression in the hepatic hilum. A complement by MRCP (Magnetic Resonance Cholangiopancreatography) revealed a significant dilation of the whole of the intrahepatic biliary arborization contrasting with a normal aspect of the main bile duct. This was caused by a tumor process from the hilar plate extending to the biliary convergence, without obstruction of the right and left main bile ducts. The description was in favor of a stage 2 Klatskin tumor according to the Bismuth classification.

The patient underwent radiological external biliary drainage. The procedure consisted of performing a catheterization of a peripheral bile duct, the opacification of which showed tight stenosis of the hilar convergence. It was not possible to pass the stenosis of the main bile duct using catheters, which led the operator to insert an 8 French external drain (Figure 1, 2).
The patient’s file was presented to a multidisciplinary consultation meeting for surgical resection. The extension assessment did not reveal any secondary locations. Histological study of which was in favor of cholangiocarcinoma. Cholangiopancreatography (ERCP) with biliary brushing, the functional origin.

of sodium through the external biliary drainage, and the renal failure correction of renal failure were noted a few days after this incident biliary drainage catheter. A remarkable rise in serum sodium and a hyponatremia at 124 mmol/L which is hypo-osmolar (254 mOsmol/Kg) as well as a renal insufficiency (urea at 1.6 g/L and creatinine at 22.1 mg/L). The average sodium concentration in the bile is around 145 mmol/L (usually varies between 122 and 164 mmol/L) [9]. In our case, the biliary drain brought back a daily volume of about 2 liters each day, which represents about 290 mmol per day, which is equivalent to a loss of about 6 g to 7 g of sodium per day, explaining the persistence of hyponatremia despite insufficient sodium per day supplementation (4 g/day).

Some situations favor the development of hyponatremia secondary to biliary drainage, including pre-existing renal pathology, use of diuretics, hepatic cirrhosis, adrenal insufficiency, and a low sodium diet [9]. Although the mechanism by which this occurs in some cases is not clear, the development of acute renal failure complicating external biliary drainage has been described in the literature [10-11]. It seems that hydrosodic depletion through biliary drainage leads to a loss of ionic reserves and consequently to circulatory insufficiency. In the context of metabolic acidosis, this will lead to a decrease in renal perfusion, parenchymal hypoxia and an alteration in tubular function in the absence of immediate and appropriate therapeutic management.

Therapeutic management of these complications requires filling with isotonic fluids containing sodium, chloride, lactate, bicarbonate, and potassium in patients with hyponatremia, and should be tailored to the volume of bile fluid and serum electrolyte levels [10]. On the other hand, good filling with octreotides and renal support with hemodialysis, have been found to be effective in the management of renal failure complicating external biliary drainage [2].

External biliary drainage in some conditions should be avoided by opting for internal biliary drainage, which has more advantages: more access to the biliary tree and no external catheter [12]. Internal drainage is preferred after certain procedures, such as hepatectomy, in which external drainage suppresses liver regeneration under certain conditions [13].

**Conclusion**

External biliary drainage can lead to major hydroelectrolytic complications, especially during high biliary flows, due to the loss of large quantities of water and solutes through the biliary drain. This situation can lead to circulatory insufficiency responsible for functional renal failure.

The interest of this observation is to search for these complications in patients having benefited from an external biliary drainage, by a clinical and biological monitoring of the signs of hyponatremia,
hypovolemia and renal failure.
